WASHINGTON

NACA WARTIME REPORTS are reprints of papers originally issued to provide rapid distribution of advance research results to an authorized group requiring them for the war effort. They were previously held under a security status but are now unclassified. Some of these reports were not technically edited. All have been reproduced without change in order to expedite general distribution.

FULL-SCALE TUNNEL MEASUREMENTS OF THE PRESSURES ON  
THE ELEVATOR AND FUSELAGE OF THE CURTISS XP-55 AIRPLANE

By Richard C. Dingeldein

INTRODUCTION

At the request of the Army Air Forces, Materiel Command, force tests and measurements of the pressure distribution over the elevator and forward part of the fuselage were made on a flying model of the Curtiss XP-55 airplane in the NACA full-scale tunnel. The results of the force tests, which include lift, drag, pitching-moment, and elevator hinge-moment measurements, have been reported in reference 1. The results of the elevator pressure measurements are given in the present paper.

The XP-55 is a low-wing airplane with the engine and propeller located at the rear of the fuselage. Longitudinal and directional control are obtained by means of an elevator located at the nose of the fuselage and by fins and rudders attached near the wing tips.

The pressures were measured over a wide range of elevator and elevator tab deflections for several angles of attack of the fuselage axis with the landing flaps retracted and deflected  $45^{\circ}$ . A few tests were made to determine the

pressure distribution over the forward part of the fuselage with the elevator removed.

An analysis has been made to show the distribution of normal-force coefficient across the span of the elevator and a comparison is given of the elevator normal-force coefficients determined from the pressure measurements and those determined from the force tests. Some calculations have been made of the fuselage normal-force coefficients by means of existing theoretical knowledge and these results are compared with the experimental data. Owing to the general applicability of the data to canard-type airplanes, the analysis has been extended to include a discussion of the mutual effects of the elevator and fuselage loadings on the normal-force distributions.

#### SYMBOLS

$\Delta p$	difference between free-stream static pressure and local static pressure
$q_0$	free-stream dynamic pressure
N	normal force
n	section normal force
S	surface area
c	elevator chord
$\alpha_F$	angle of attack of the fuselage axis relative to free-stream direction, degrees

$\delta$	control-surface deflection, degrees; positive with trailing edge down
$c_n$	section normal-force coefficient, $n/q_c$
$C_N$	normal-force coefficient, $N/qS$
$C_L$	lift coefficient, $L/qS$
$\frac{dC_{N_e}}{d\delta_e}$	elevator effectiveness
$\frac{dC_{N_e}}{d\delta_T}$	elevator tab effectiveness

Subscripts:

e	elevator
f	wing flap
T	elevator tab
F	fuselage

#### APPARATUS AND TESTS

The flying model of the Curtiss XP-55 airplane, which is designated the Curtiss model 24B, is shown mounted in the NACA full-scale tunnel in figure 1. A three-view drawing giving the important dimensions of the airplane is shown in figure 2. The elevator which is hinged at 13.42 percent of the chord, has a symmetrical low-drag airfoil section that was developed by the manufacturer. The elevator is equipped with trim tabs having a span of 50 percent of the elevator.

span and a chord of 25 percent of the elevator chord. The elevator was directly connected to the stick, but the tab angle was adjusted by means of a separate control in the cockpit.

Flush-type static-pressure orifices were installed in the left elevator and tab and in the left side of the fuselage. The inside diameter of the orifice tubes was 0.090 inch. The location and identification of the orifices are given in tables I to III and in figures 3 to 5.

All the tests were made at a tunnel airspeed of approximately 63 miles per hour and with the airplane propeller removed. Pressure measurements were taken for various elevator deflections with the elevator tab neutral at angles of attack of the fuselage axis of  $0.9^\circ$ ,  $4.6^\circ$ ,  $12.0^\circ$ , and  $15.8^\circ$ . The effects of deflecting the elevator tab on the pressure distributions over the horizontal tail surfaces were determined at angles of attack of  $0.9^\circ$  and  $12.0^\circ$ . Most of the tests were made with the landing flaps retracted; however, a few tests were made with the flaps deflected  $45^\circ$ . The complete test program is listed in table IV.

#### RESULTS AND DISCUSSION

The test results (tables V and VI) have been corrected for jet-boundary effects (reference 2), the longitudinal static-pressure gradient in the jet, and stream angle and

blocking effects at the elevator (reference 3), and therefore differ slightly from the data presented in the preliminary reports. Chordwise pressure distributions over the elevator and forward part of the fuselage were plotted from these data. Integration of the chordwise pressure distributions gave the distribution of normal-force coefficient across the horizontal tail span which was then integrated to obtain average values of elevator and fuselage normal-force coefficients. In the determination of the spanwise normal-force distribution, the chord of the fuselage has been taken as 29.8 inches, which corresponds to the chord at the elevator-fuselage juncture. The elevator normal-force coefficients are given in table IV.

Chordwise pressure distributions. - Isometric charts of typical chordwise pressure distributions over the elevator and forward part of the fuselage are presented in figures 6 to 19. The effects of the elevator and fuselage loadings on the resultant pressure distributions are clearly shown in these figures. The normal force on the fuselage increases for positive deflections of the elevator and decreases for negative deflections of the elevator. A greater percentage of the normal force on the horizontal tail surface is carried across the fuselage when the tab is deflected with the elevator neutral than when the elevator is deflected with the tab

neutral inasmuch as the gap between the elevator and the fuselage is smaller for tab deflections than for elevator deflections. The load on the fuselage directly affects the load on the elevator such that, at high angles of attack of the fuselage, the pressure differences between the upper and lower surfaces of the inboard section of the elevator are increased, whereas the outboard sections are not appreciably affected. (See figs. 7 and 16.) It should also be noted that at positive angles of attack of the fuselage the pressures near the trailing edge of the elevator are more negative for the inboard sections than for the outboard sections.

At  $\alpha_F = 12.0^\circ$  and  $\delta_e = 10^\circ$  (fig. 13), stall occurred over the center section of the elevator, but the fuselage remained unstalled. At an angle of attack of  $12.0^\circ$  (fig. 16), an elevator deflection of  $-10^\circ$  would be expected to result in a smaller elevator loading than is shown inasmuch as the angle of the elevator with respect to the free-stream direction is only  $2.0^\circ$ . The high elevator loading for this condition is due to the effects of the upwash ahead of the wing and the fuselage-pressure distribution. The upwash due to the wing increases the effective angle of attack and the normal-force coefficient of the elevator. The pressure differences between the upper and lower surfaces of the fuselage extend across a part of the elevator and tend to increase the negative

pressures on the upper surface at the rear of the elevator. These effects increase with angle of attack and cause the elevator to float nose down with respect to the free-stream direction.

The static-pressure differences between top and bottom longitudinal sections of the fuselage are plotted in figures 20 to 22 for various angles of attack with the elevator and tab neutral. The longitudinal location of the elevator with respect to the fuselage is drawn to scale in each figure. The elevator floating angles determined from the force tests are shown in figure 23. At  $\alpha_F = 12.0^\circ$ , the elevator floats at  $-7.0^\circ$  with respect to the free-stream direction. The floating angles for any particular angle of attack shown in figure 23 are  $1.5^\circ$  less than those given in reference 1. This discrepancy represents a correction for the difference in the average stream angle across the elevator and wing span which has been applied to the data.

Span-load distribution. - The distribution of normal-force coefficient across the span of the elevator for the various test conditions is shown in figures 24 to 29. The loading across the fuselage shown in these figures represents the increment of normal-force coefficient due only to the presence of the elevator and was determined from the difference in the pressures on the fuselage with the elevator attached to the airplane and with the elevator removed.

The spanwise distributions of normal-force coefficient for various elevator deflections with the tab neutral and for various tab deflections with the elevator neutral at  $\alpha = 0.9^\circ$  are shown in figures 24 and 25. A comparison of these figures shows that a tab deflection equal to twice that of the elevator produces very nearly the same load on the horizontal tail; that is, the total load on the horizontal tail surface produced by a  $-10^\circ$  tab deflection with the elevator neutral is very nearly equal to that produced by a  $-5^\circ$  elevator deflection with the tab neutral. (See fig. 26.) In addition, these figures show that for a given tab deflection, the fuselage and the inboard section of the elevator are more highly loaded than for an elevator deflection producing the same normal-force coefficient. Figures 27 to 29 show the spanwise distribution of normal-force coefficient at angles of attack of  $4.6^\circ$ ,  $12.0^\circ$ , and  $15.8^\circ$  for various elevator deflections with the tab neutral.

The effect on the elevator span loadings of deflecting the wing flaps  $45^\circ$  at fuselage angles of attack of  $0.9^\circ$ ,  $4.6^\circ$ , and  $12.0^\circ$  (figs. 30 to 34) is small. Reference to the force tests (reference 1) showed that the average increment of lift coefficient due to this flap deflection was only about 0.23; hence, the upwash at the elevator due to deflecting the wing flaps is small.

Normal-force coefficients. - A summary of the average elevator normal-force coefficients obtained from the span-load

distributions of figures 24 to 34 is given in table IV. A comparison is made in figure 35 of the elevator effectiveness,  $\frac{dC_{Ne}}{d\delta_e}$ , determined from the pressure distributions and from the force tests at four angles of attack from  $0.9^\circ$  to  $15.8^\circ$ . The elevator effectiveness obtained from the force tests was determined by comparing the pitching moments of the airplane with the elevator removed and attached. The elevator effectiveness obtained from the pressure measurements was 0.042 at all angles of attack as compared with an average value of 0.040 determined from the force tests.

The small difference between these values of  $\frac{dC_{Ne}}{d\delta_e}$  probably results from the change in pitching moment of the inboard section of the wing due to the elevator trailing vortices. At  $\alpha_F = 15.8^\circ$  the value of normal-force coefficient determined from the force tests at any elevator deflection was about 0.14 greater than that determined from the pressure measurements although the slopes,  $\frac{dC_{Ne}}{d\delta_e}$ , were approximately equal. This discrepancy probably results from the fact that part of the wing was stalled at this angle of attack.

Values of the normal-force coefficient of the elevator for various tab deflections with elevator neutral at an angle of attack of  $0.9^\circ$  are presented in figure 36. The

tab effectiveness,  $\frac{dC_{N_e}}{d\delta_T}$ , determined from these results is 0.024. This value is about one-half as large as the elevator effectiveness.

The fuselage normal-force coefficients determined from the pressure data with the elevator removed are given in figure 37. A comparison has been made of these values and normal-force coefficients calculated by the methods presented in reference 4. Although the slopes,  $\frac{dC_{NF}}{d\alpha_T}$ , are in fairly good agreement, the results based on the pressure data indicate that there is a small upload on the fuselage at zero angle of attack of the fuselage axis.

#### SUMMARY OF RESULTS

1. The elevator effectiveness,  $\frac{dC_{N_e}}{d\delta_e}$ , obtained from the pressure measurements was 0.042. This value was in good agreement with that determined from force tests.
2. The effectiveness of the elevator tab was about half as great as the elevator effectiveness; a value of  $\frac{dC_{N_e}}{d\delta_T}$  of 0.024 was measured.
3. The change in the elevator normal-force coefficient resulting from deflecting the wing flaps  $45^\circ$  was small.
4. The normal-force coefficients of the inboard sections of the elevator increased as the loading on the forward part of the fuselage increased.
5. A greater percentage of the normal force on the elevator surface was carried across the fuselage when the tab was

deflected with the elevator neutral than when the elevator was deflected with the tab neutral inasmuch as the gap between the elevator and the fuselage was smaller for tab deflections than for elevator deflections.

6. The pressure measurements indicated that the elevator will tend to float nose down with respect to the free-stream direction due to the effects of fuselage interference and wing upwash.

Figure 1.- The XP-55 airplane mounted in the full-scale tunnel.

Areas, sq. ft.

Wing (including flaps)	203.4
Aileron (total)	13.10
Flaps (total)	14.85
Rudder (each)	6.61
Wing fin (each)	8.80
Upper cow fin	7.88
Lower cow fin	4.26
Elevator (including fuselage)	18.00
Elevator (excluding fuselage)	12.78
Elevator tabs (total)	2.25

*Gross weight 4000 pounds*
